1.0 RADAR SECTION – SEARCH SETS

This document intends to explain the Radar, IFF and Sonar systems that were used aboard HMCS HAIDA from the time of her commissioning in August 1943 until she paid off in October 1963. The term ASDIC will be used instead of SONAR sonar where it is historically appropriate. The various pieces of equipment in each section are not listed in any particular order.

1.1 INTRODUCTION

Radar was the name given during World War II to an electronic system in which radio waves were bounced off a target in order to detect its presence and locate its position. RADAR is an acronym derived from the fuller term RADIO Detection And Ranging. A large number of researchers helped to develop the hardware and techniques of radar, but the development of the earliest practical radar system is usually credited to the British scientist, Sir Robert Watson-Watt. The German, Italian and Japanese navies all deployed radar systems of their own but they were substantially less advanced and much less effective than those used by the Allies. The concept of detecting an aircraft was considered so important, that each country kept the implementations very secret.

RDF (Radio Direction Finding) was the acronym used by the Brits as an attempt to disguise radar technology from the Axis powers. The acronym RADAR was created by Lieutenant Commander Samuel M. Tucker USN and F. R. Furth in November 1940, for a two-way, pulsed transmission system, although it was not accepted by all the Allies until 1943. Thereafter it received general international acceptance.

One of the most important advances made during radar development was the invention of the cavity magnetron in 1940 by Sir John Randall and Henry Boot. This device generated high-power pulses in the microwave region of the radio spectrum and was small enough to be held in the palm of the hand. Originally, the cavity magnetron was made from copper and it simply melted after short use. By testing various metals, Randall and Boot eventually settled on molybdenum as the best choice of material for the cavity magnetron. This was a silver-white, brittle metal with a high heating point. The magnetron could generate pulsed powers of 500 kW in the S band (10 cm) and 150 kW in the X band (3 cm)

Another advance in radar was duplexing, a method still in use today. This is a switching technique that allows the same antenna to be used for both transmission and reception by blocking the receiver during transmission periods. In addition, the echo signals are displayed on a CRT that uses a radial time-base that rotates in synchronism with the aerial. Since the targets appear in their correct plan positions relative to the radar station, this form of display is named the Plan Position Indicator (PPI).

This is the same type of 10 cm magnetron brought to North America by the Tizard Mission in 1940. This specific example is Canadian Type 8 BX s/n 19152. It was manufactured by Northern Electric for Research Enterprises Ltd, a Canadian Crown Corporation. One of the filament leads is missing. *(Photo by Jacques Hamel, VE2DJQ, Le Musée Québécois de la Radio)*

1.2 OPERATION

In radar, a transmitter produces radio waves, which are then radiated from an antenna which "illuminates" the airspace with those waves. A target, such as an aircraft or ship, that enters this space, scatters a small portion of this radio energy back to the antenna. This weak signal is amplified and displayed on a cathode ray tube (CRT) where it can be studied by a trained operator. Once the presence of the target has been detected, its range and bearing must be measured. Because radio waves travel at 186,000 mi/sec or 328 yards per microsecond, distance can be determined by measuring the time taken for a radio wave to travel from transmitter to the target and back to the receiver. In pulse radar, the radiation is not continuous but is emitted as a succession of short bursts, each lasting a few microseconds. A wide pulse is desirable because it delivers more energy and results in stronger signal return for the receiver. Wide pulses also have a disadvantage -- they limit the minimum distance at which targets can be detected. While the pulse is being transmitted, the receiver input must be blocked to prevent electrical damage from the transmitted pulse and to avoid false target indications. If a target is located close to the set, its echo might return while the receiver is still blocked. In this scenario, no target indication would be shown.

This transmitted pulse of radio energy is emitted upon receipt of a firing signal from a trigger unit that simultaneously initiates the time-base sweep on the CRT. Once the electronic clock is started, and when the echo signal arrives on the tube, the time delay can be measured thus calculating the range. Pulses are emitted at the rate of a few hundred per second and the operator sees a steady signal on the CRT.

There is one disadvantage of using a high pulse repetition rate. Once a pulse is sent out, sufficient time must be allowed for the echo to be received. If another pulse is sent out before the first one is received, false indications will be displayed. The pulse repetition rate, therefore, determines the maximum workable range of the radar set.

CHAFF

Researcher Robert Langille provides this short passage regarding CHAFF and HAIDA's relevance to it. "The development of chaff as a radar countermeasure started in the Second World War by both the British and the Germans –each unaware that they discovered the same secret. In July 1942, Lady Joan Curran investigated the idea of generating a cloud of false radar echoes by dumping packets of aluminum stripes from an aircraft. The invention originated from the idea by Doctor Reginald Victor (R.V.) Jones in 1937, that a piece of metal foil (Dipole) cut to half the wavelength of the transmitter radar frequency could be used dispersed from aircraft and create false target echos to deceive enemy radar operators. The invented device was codenamed Window by the British, Chaff by the Americans, and Duppel in Germany (named for the Berlin district where the first tests took place in 1942). However, Duppel saw limited use by the Germans during World War II as Field Marshall Goering thought it would invite retaliation. Thus, he ordered subsequent technical records destroyed. The decision not to use the Window application was a much debated and well-kept secret by the highest levels in Allied Command. It wasn't until early 1943 that Prime Minister Winston Churchill approved and authorized its use. A couple of weeks later, Window was first used by the Royal Air Force (RAF) during Operation GOMORRAH – the devastating air-raids On Hamburg. During this operation, 90million aluminized paper strips were dispersed, each measuring 12 by 0.6 inches. Window greatly contributed to the confusion of the Wurzburg radar system and its operators, blinding them almost completely and rendering the German air defence batteries useless.

Out of the 791 RAF bombers deployed, only 12 did not return, whereas in previous missions, without the use of Window, more than 10% of the aircrafts had been lost. For a long time, Window was only used to attack the German Wurzburg radar systems. Quite notably, and along with other deceptive devices, it was later used to provide the two false-target (fictitious) fleets during the D-Day invasion components of Operations Glimmer and Taxable. The success of these operations was greatly contributed to by the Canadian destroyer HMCS Haida, which was designated as the lead ship for trials off the coast of Scotland a couple of months prior to the planned invasion. Haida, along with the Sterling and Lancaster bombers and smaller seaborne vessels, conducted extensive and successful testing trials which led to the enabling and success of these two operations". (The Haida reference is from the book " Bodyguard of Lies by Anthony Cave Brown. The actual mention is at the end of Chapter 8"

1.3 Type 271 - Air/Surface Warning Set

Antenna location: After boathouse

Equipment location: Some electronics on the back side of the antenna. Suspect the operator sat directly under the 271 since the antenna was rotated manually. Installed: During the January 1944 refit in Plymouth

Removed: During November 1944 refit in Halifax.?

While the SW1C prototype was being tested in HMCS Chambly, a new air/surface warning set, namely the 271, was being tested aboard a Flower class corvette, HMS Orchis in England on 25 March 1941. The 271 set, using the cavity magnetron, operated on ten centimetre wavelengths (3030 MHz) at a power level of 5 kilowatts, was keyed by 1.5 microsecond wide pulses at a PRF of 500 Hz. This was quite a breakthrough in technology for the time, however it only used a ranging display (A scope), a rather inefficient means for a search radar. Its finer and narrower beam (5 degrees H by 20 degrees V) would permit escorts to detect trimmed-down U-boats at long distances, consistently and accurately. Sea trials indicated that the 271 could detect a trimmed-down submarine at 3,500 yards and a periscope at 900 yards. A battle ship was detectable at 13 nm.

271 set. (Photo courtesy HMS Collingwood Radar Museum)

After the British provided a "gift" magnetron to the USA in November 1940, progress there was also very rapid. The Type SG set designed by Raytheon went to as a prototype in a destroyer with a display using a Plan Position Indicator (PPI) in June 1941. The SG worked on a frequency of 3175 MHz with a 50 kW output.

By the spring of 1943, the large majority of mid-ocean escorts were fitted with the 271, however, many ships of the Western Local Escort Force were not. To complicate matters, the British introduced two improved models, namely, the 271P and 271Q. Both of these versions had output

power increased from 8 kilowatts in the 271 to 90 kilowatts in the 271Q. This quantum jump in power output can be directly attributed to a major improvement in magnetron technology. While the RCN was struggling to fit new ships with first generation 271's, they were also under great pressure to upgrade existing radars. By September 1943, only fourteen 271Q sets and fifty three 271P's were fitted into RCN vessels along with three original production models. The introduction of 10 cm radar into fleet destroyers was delayed until the needs of the escorts were satisfied.

Since the 271 set operated at the 10 cm wavelength, the antenna could be made small enough to be housed in its own Perspex bubble and mounted on top of the operator's cabin. The antenna consisted of a 'double cheesecake' with separate transmitting and receiving antennas stacked one on top of the other. This radar was sometimes called 'lighthouse' due to the shape of the dome. Some of the transmitting and receiving elements had to be affixed directly to the back of the antenna to overcome co-axial line losses. In the original 271, the power feed to the antenna was by coaxial cable so this limited rotation to 200 degrees. When the original magnetron was redesigned to produce higher power, waveguide was introduced to the antenna system. Coaxial cable could not handle those power levels.

Initially, the new 271 set was viewed with suspicion by the crews of the ships in which they were installed. Noting that the ratings were reluctant to go aloft, especially to the crow's nest just above the 'lighthouse', the captain of a ship in which a new 271 radar had just been installed questioned a seaman as to the reason. After a bashful amount of toe stubbing, the sailor confessed that the 'buzz' was that rays from the set would make a man impotent. Nipping an incident in the bud, the quick witted captain declared the rumour to be nonsense. "Radar rays", he maintained, "made a man temporarily sterile, not impotent". From this viewpoint, it was viewed as a bonus rather than a drawback especially on shore leave. The 271 then became the most popular piece of equipment in the ship.

A 271 set (variant unknown) was installed on HMCS Haida during her January 1944 refit while she was in Plymouth. The radar hut was located astern between the searchlight and the pom-pom guns. An integral, perspex, "hat-box" antenna was mounted directly above the 271 office.

Perspex enclosure for the 271 radar antenna. This is a recreated enclosure found on HMCS Sackville.
(Photo by Jerry Proc)

271 antenna front view. There were two, cheesecake style parabolic reflectors mounted on top of each other. One was for receive and the other for transmit. The antenna was manually trained by a hand wheel in located in the radar office. *(Image source unknown)*

1.4 Type 291 - Air Search Set

First antenna location: Foremast top in 1943.

First Equipment location: In an office on the Flag Deck below the bridge in 1943.

Second antenna location: Relocated to mainmast top in 1944

Second equipment location: 291 moved to the Second Wireless Office

Removed: During 1950-52 modernization

This was the final British 214 MHz (P-Band) small ship, air search radar that was introduced in 1942. Early versions of this set required separate transmitting and receiving antennas, but a TR box was soon developed. The antenna was similar in concept to that of a 281 type, but the dipoles were supported by an X-shaped structure. This antenna had a beam width of 40 degrees and was of the lazy 'H' construction. Power output was 100 kilowatts at a pulse length of 1.1 microseconds. PRF was 500 Hz. It had the capability of detecting a bomber at 15 nm.

By 1944, type 291 was fitted to nearly all British destroyers and lesser escorts. Its installation time was seven days. The M, P and Q versions had powered rotation for the antenna and PPI displays in addition to the 'A' scopes. Type 291U, developed for coastal forces and trawlers, had a special lightweight aerial consisting of a pair of superimposed Yagis. It could detect a submarine at 1.5 nm. Another variant, the 291W, was designed for submarines with a rotating aerial that had to be watertight and withstand hydrostatic pressure.

Eventually, the 291U and W sets were replaced with the model 267W. As for the 291, it remained in service in destroyers until about 1952 after which destroyer air search was restricted to coverage provided by the 293 set, the target indication radar.

Both the 291 and 293 sets were fitted on HMCS Haida simultaneously. Les Taylor of Walsall England, a former radar mechanic on Haida, recalls the details of the fitting. "The 291 office was located on the flag deck below the bridge. The antenna, which was located at the top of the foremast was fed by Pyrotenax cable. This coaxial type cable consisted of a centre conductor surrounded by a powdered, ceramic-like compressed insulating material. The centre conductor and the insulation was enclosed within a hollow copper tube. If, for any reason, moisture entered the cable, its insulation properties fell below acceptable limits and required the occasional treatment with a blow torch to drive out the moisture.

During my service on HAIDA, I was solely responsible for maintenance, range calibration, and repair of the radar equipment. There was no one that I could turn to for help, advice or to discuss technical problems. Slightly short of my eighteenth birthday, and being the youngest person aboard, I was supposed to be the expert. The technical radar school at HMS Valkyrie on the Isle of Man had many rooms containing radar equipment for either large or small ships. We were given a training choice on particular radar types that were fitted on large or small ships. Afterwards, we were drafted to those particular ships upon the completion of our training. I chose small ships. How lucky! "

291 Antenna. It is not known what version of 291 set was fitted to HAIDA. *(Photo courtesy CB 4182/45 Radar Manual)*

1946: The 291 radar was co-located in the Second W/T office after late 1944. Above - 291 transmitter; 291 receiver; 291 indicator; Aerial control under indicator. Power supply board for outfit DUF (under aerial control); PPI; 242 IFF modulator, mixer, transmitter, IFF responder below PPI. On starboard bulkhead, PPI control board; 242 IFF control board. (RCN Photo HS 1749-67)

1.5 Type 293M - Warning Combined Type

Antenna location: Foremast, teardrop platform

Equipment location. Port side , main deck , across from the galley in the space now occupied by the EMR compartment.

Installed: May have been installed during HAIDA's 1944 Canadian refit ?

Still aboard in 1958, but perhaps not being used.

Removed: By 1960 ?

This type was an S-band target indicator (sometimes referred to as 'Warning Combined' type) using the same transmitter as the 277 and was equipped with the new, azimuth stabilized, 'cheese' antenna. It acquired that name because it looked like a block of cheese cut in half. Stabilization was necessary otherwise, the roll of the ship would tilt the 'fanned' beam and air targets might be displayed at wildly wrong bearings. The beam was wide in the vertical plane so that the ship's roll would have little effect. Typical detection range was 15 nm for an aircraft at 10,000 feet. Type 293M, which incorporated an 8 foot antenna, was introduced into service in 1945. 293P was similar to the previous model but it was modified for easier maintenance. A post-war radar program introduced the 293Q set with a redesigned 12 foot antenna. HAIDA was fitted with the 293M type until the late 1950's.

In Korea, 293 radars were operated in accordance with an Electronic Emission Control (EMC) policy. This meant that the radar could be turned on for a 3 minute duration for every 15 minute interval since the 293 was detectable by warning devices. It was assumed that the Koreans had such devices so the 293 sets were used for short periods of time only. High Definition Warning Sets (HDWS) radar was not detectable and required no such precautions.

The AQR antenna used to be a shore exhibit when HAIDA was still in Toronto (*Photo by Jerry Proc*)

Operations Room Aboard HAIDA in 1946: Forward bulkhead showing the 293M PPI slave display. Through a large magnifying glass fitted in the deckhead of the Operations Room starboard side, bridge personnel could read the plot table and the PPI display. The front of the PPI display is shown with the mirror mounting frames folded back and in the stowed position. When in use, the frame was extended and a mirror would be inserted into the frame and positioned so the screen could be viewed from above. The Plot Table is shown with the dust cover in place. (RCN photo #1749-56)

293M Office. Starboard bulkhead: 230 volt, 50 cycle, 3 phase power board; DUG Motor starter; Power board for DUG (180 volt, 500 cycle); Board Distributing 2-AM (*RCN photo # HS1749-52*)

293M office. After bulkhead: 293 transmitter; Output unit; P51 receiver; modulator; 253P IFF controls over modulator. On the port bulkhead, receiving panel L26; Wavemeter G82A and anti-wave clutter unit over L-26; aerial controls unit 20H below. (RCN photo # HS1749-53)

293M Office. After bulkhead: 293 transmitter; modulator; On the port bulkhead, 253P IFF (extreme left of photograph) 242 IFF responder, performance meter, modulator and mixer; Receiver panel L26, with wavemeter G82A and anti-wave clutter unit; AQR aerial control table (front cover removed to show control unit 20-H). (RCN photo # HS1749-54)

293M Office. Port bulkhead: PPI Unit; ranging outfit RTE including panel L-37 and two strobe generators; cathode follower unit is below RTE. (RCN photo # HS1749-55)

293 Office, 1946: Target Indication Room - after bulkhead.
Ranging outfit RTB including panel L-37 and two strobe generators. TIU/PPI displaying 293M;
Outfit JH-1 (panel L-43); PPI control board and 242 IFF aerial indicator (over TIU). (RCN photo
HS 1749-58)

1.6 Sperry MK II Navigation Radar

Antenna (scanner) location: Midway up the foremast.

Equipment location: PPI display and control unit in Operations Room

Transmitter and receiver in the AN/SPS-6C compartment

Installed: 1952

HAIDA paid off with this type

This was a medium range, surface search radar designated as a High Definition Warning Surface (HDWS) set. From the early 1950's, until well into the 1970's, almost every ship in the RCN was fitted with the Sperry Mk 2. Although its primary use was to locate other ships, helicopters, navigation aids and shorelines, it was very effective in detecting submarine periscopes. This type was fitted aboard HAIDA. After life expiry, the Mk II was replaced by the Sperry Mk 127E solid state radar.

Peak power:30 kilowatts

Operating frequency: 9375 MHz +/- 45 MHz

Pulse length: 0.25 microseconds

Pulse repetition rate: 1000 pulses per second

Scanner rotation rate : 15 rpm

Beam Width: Horizontal - 2 degrees

Vertical - 17 degrees

Range markers: Fixed 0.5, 2, and 5 mile intervals +/- 1%

Variable - 0.3 to 20 miles +/- 2%

Range scales:1, 2, 6, 15 and 30 miles

Resolution: For range:80 yards; For bearing - 2 degrees

Indicator CRT size: 12 inch diameter

Dimensions and Weights: Indicator - 27"D x 20"W x 51"H ; 350 lbs

Scanner:20"L x 50"W x 49.5"H ; 300 lbs

Tx/Rx: 26.5"D x 22"W x 17"H ; 190 lbs

Power requirements:115 VAC 60 Hz, 1000 watts

Contractor: Sperry Gyroscope, Great Neck, N.Y

Vintage: May 1953

This is the Sperry MkII PPI display as fitted in the Ops Room of HMCS HAIDA. *(Photo by Jerry Proc)*

Location of the Sperry MK II scanner (antenna) on the foremast. *(Photo by Jerry Sullivan)*

1.7 AN/SPA-4 PPI Indicator

Location: One in the AN/SPS-6C compartment and a slave unit on the bridge..

Installed: 1953 +/-

HAIDA paid off with this type

The Range-Azimuth Indicator AN/SPA-4 was a self-contained unit that was designed for operation with any naval search radar system having a pulse repetition frequency between 140 and 3,000 pps. This indicator was capable of receiving radar information from one of eight different radar systems as selected by a front panel control but this feature was not used in HMCS HAIDA . On HAIDA there was an externally mounted selector switch that was used to select the radar input source. The SPA4 employed a remote PPI type indicator using a 10 inch, flat CRT.

Azimuth was determined by means of a mechanical cursor coupled to an electronic cursor jointly they were accurate to within one degree. Azimuth information was also indicated by a mechanical counter when the cursor was moved. Range information was obtained from range rings that could be displayed at intervals of 0.5, 1, 2, 5, 10, 20 and 50 miles. Range could also be measured by a mechanical counter. An electronic range strobe was accurate to within 1 percent of the maximum range being viewed.

The SPA-4 was also capable of transmitting electrically, the bearing and range information to other systems such as fire control or directly to a projector on the plot table. That would cut down on verbal communication. The unit on the bridge could be slaved to either the SPS-6C or the Sperry Mk II radars.

SPECIFICATIONS

Range selection: 1.5 to 300 miles continuous using a centered PPI and limited by the pulse rate of radar set that it was connected to.

Weight : 378 pounds

Dimensions: 38" H x 19" W x 21" D

Power requirements:120 VAC, 60 Hz at 10 amps

Contractor: RCA Victor Company, Montreal P.Q.

Contract number: FE 113375, A/T 2-P-1-1877

Vintage: September 1953

1.8 VK5 PPI Indicator

Location: Operations Room

Installed: 1956?

HAIDA paid off with this type

This was a PPI radar display and one unit was installed in HAIDA's Operations Room. It had a 10 inch CRT and its primary feature was the ability to offset the sweep from the centre of the screen. The VK5 contained 101 vacuum tubes. It could be switched between the AN/SPS6-C air search and Sperry Mk II radars in order to display targets of interest.

This VK5 example can be found aboard HMCS HAIDA. (Photo by Jerry Proc)

1.9 AN/SPS-6C Air Search

Antenna location. On its own dedicated platform on the foremast.

Equipment location: In the SPS-6C radar compartment, port side, above the galley. Switchable PPI displays in the Operations Room and bridge.

Installed: 1953. (HAIDA sailed to Korea on her second tour of duty with SPS-6C installed). HAIDA paid off with this type

The radar set AN/SPS6-C was a shipborne, long range, air and surface search type designed to supply target bearing and range data to its five inch A-scope indicator. In addition, as many as four, external, PPI indicators of the Radar Indicating Equipment VE, or Radar Repeater Equipment VJ or VK types could be attached to the SPS-6C. The RCN called this system WA

meaning Warning Air. In 1947, the SPS-6 was granted AN nomenclature and the initial sets were procured from Westinghouse by the US Navy. Following quickly in 1947 were the 6A and 6B variants. The 6C and 6D versions were introduced in 1951, and the final 6E model in 1964. The antenna was a unidirectional, parabolic type reflector, equipped with a wind balancing vane and had a characteristic 30 degree cosecant pattern in the vertical plane. Horizontally, the beam width was 3.5 degrees. Its rotational period was 5 to 15 RPM in automatic mode and up to 2.5 rpm in manual mode. A dual feed horn on the antenna transmitted and received both radar and IFF signals. Overall weight for the antenna and its mounting pedestal was 924 pounds. The antenna itself weighed 591 pounds. Contrast that with the weight of the system cabinet which tipped the scales at 1,063 pounds.

During the life of this system, there were four major American procurements. The first two were awarded to Westinghouse of Baltimore Md, the third went to AVCO Mfg/Crosley Division of Evandale Ohio and the final procurement was given to Stromberg- Carlson of Rochester, New York. Quantity and years of procurement by the RCN are not known at this time. HMCS HAIDA was fitted with AN/SPS-6C at the time she was paid off. It was originally fitted on her second tour of duty to Korea.

AN/SPS-6C SPECIFICATIONS

Frequency range: 1250 to 1350 MHz

Power output: 500 to 750 kilowatts

Pulse repetition rate: One pulse rate is 150 pps with a pulse width of four microseconds. The other pulse rate is 600 pps with a pulse width of one microsecond. The pulse rate could be varied +/- 10 percent from each of the two frequencies given above, by means of a calibrated front panel control.

Receiver type - Superheterodyne type; 30 MHz IF
Equipped with automatic frequency control and anti-jamming features.

Range markers: The 'A' scope had range markers of 4, 20, 80, and 200 miles

Indicator types The system was designed to interface to either VE, VF or VG type equipment

Power requirements: 115 or 440 VAC, 60 Hertz at 5.5 kilowatts

AN/SPS-6C major system components. (Photo courtesy Westinghouse Electric Corporation)

2.0 RADAR SECTION - GUNNERY

2.1 Type 285 Fire Control System

Antenna location: 6 Yagi antennas mounted atop a rangefinder.

Equipment location: At the base of the foremast. Fitted on-build in 1943.

Removed: During the 1950-52 modernization and upgrade to the Mk 63 Fire Control System.

This was a secondary-battery gunnery radar, first fitted aboard ships in 1941. It employed two types of aerial arrays; one with six Yagi's and the other with five Yagi's. In the six Yagi version, three aerials were used to transmit and three to receive. This arrangement produced a narrower 18 by 43 degree beam. HAIDA was fitted with the six Yagi array. Bearing accuracy was 3 to 4 degrees typical, with an accuracy of 100 yards on the 15,000 yard scale. This 25 kilowatt set was keyed by 1.7 microsecond pulses and operated at a 50 cm wavelength. At maximum range, it could detect a cruiser at 7 nm. On Haida, the 285 set was fitted-on-build (1943). The gunnery office was located at the base of the foremast while the aerial was mounted atop the director control tower on the bridge. The 'P' variant was an improvement on the original design with the introduction of a transmit/receive switch (T-R) which permitted the use of a common antenna. Beam width was reduced to 9.5 degrees along with a reduction in pulse width and higher transmitter power. The Auto Barrage Unit (ABU) which was associated with the Ranging Panel L22 was also installed. ABU was fed with range and rate of change information from the L22 panel and using a mechanical calculator, provided the 'instant of fire' for range settings on the fuses in use.

By the time of Haida's commissioning, the Destroyer Director Control Tower (DCT), which had been fitted on the first British Tribal class destroyers, had become obsolete. Instead, the entire fire control of the main armament centered on a variant of the Rangefinder Director, known as the Mk III (W). This was similar to the Mk II (W), which on the earlier Tribals, had been utilized as a director for AA fire only. Information from the Mk III (W) was fed to the Transmitting Station, along with information from 285 radar. The DCT was staffed by a crew of five: Control Officer, Rate Officer, Layer, Trainer and Rangetaker.

Information from the Rangefinder was fed into two mechanical predictors a.k.a. clocks. One was the Admiralty Fire Control Clock (AFCC) and the other was the Fuze Keeping Clock (FKC). The AFCC controlled fire at surface targets, while the FKC controlled fire at aircraft targets. It was in the Transmitting Station that the "fire control solution" (FCS) was generated. The FCS was the gun bearing and elevation angle for the gun barrels. The guns were fired when the control officer in the DCT pushed a button.

In the early 1950s, Haida, like the other Canadian Tribals, had their Rangefinder Directors replaced with the Mk 63 Fire Control System, which was an American design. This was mounted in the unoccupied DCT position on the bridge. It was an independent unit, incorporating its own AN/SPG-34 radar. The aerial was mounted on the elevating gun cradle and full "blind fire" tracking against unseen targets could be carried out. Today, all that's left of the DCT is an empty steel shell. HAIDA paid off in December 1949 to commence her mid-life modernization. As a result much of her WWII fittings were removed. The ship recommissioned on March 15, 1952.

The 285 came in two configurations. Pictured above is the FK (Fuze Keeping Clock) configuration. This was the system installed in HAIDA in 1943. (Royal Navy Graphic)

285 radar antennae atop the Mk IIIW rangefinder. (Image from CB 4182/45 Radar Manual)

Unfortunately, the 285 was fundamentally flawed due to its inability to follow aerial targets in elevation and was replaced with the model 275. As the director was manually controlled, it was difficult to follow fast moving aircraft.

2.2 AN/SPG-34

HAIDA had two independent SPG-34 antennas and Mk 63 Fire Control Systems.

Antenna locations: One atop 'B' Gun and one atop the 3"50 gun.

Equipment location: Forward position - In a separate compartment on the starboard side, Flag Deck. Aft position - In a separate compartment behind the Armourers Workshop. Installed:

During 1950-52 modernization.

HAIDA paid off with this type.

SPG-34 is an X-band fire control radar for AA guns. It measured the range from the gun to the target and the value derived was used to calculate the lead-off angle of the gun. The antenna was

a 40 inch diameter dish that could produce a 2.4 degree beam. Power output was 25 to 30 KW with a range of 25,000 yards.

3.0 IFF SYSTEMS

The IFF acronym is derived from the words Identification, Friend or Foe. Sometimes it was called Radar Identification and Recognition System. Starting with the Mk I system in WWII, IFF initially started with its own separate equipment and antennas and had some limited direction finding capability. In later developments it was incorporated to work with the main radar search antenna. Today, the IFF interrogator is embedded in the feedhorn (or a secondary antenna 'bolted' to the parent) of the radar antenna and as the radar sweeps and hits a target it challenges it at the same time. The operator on the radar set sees an IFF squawk on his PPI. The latest equipment using the Mk 12 protocol displays all kinds of information to the challenger.

When IFF is being used, the searching radar automatically sends interrogating pulses. This is accomplished by having the IFF dipole antenna mounted across the opening of the feed horn of the radar antenna. The IFF unit in a friendly target will automatically respond with the correct reply and the reply is made visible on the screen of the interrogating radar.

British IFF systems were coded into two series during World War II; the 240 series was used for interrogators and the 250 series for responders and beacons.

IFF DEVELOPMENTS OVER TIME

MK I AND MK 2 IFF'S

In 1940, the MK I system was introduced in British service. Its details were disclosed to the United States that fall, but this system was already obsolete. Quite independently, the Naval Research Laboratory (NRL) had developed a pulse transponder in 1939. To challenge, the radar was switched to a special pulse repetition frequency (PRF) which triggered responses. In US Service, the CXAMM IFF system was considered equivalent to the British Mk II. So far, the radar itself was the interrogator. Since the interrogator and transponder operated on the radar frequency such operation was not satisfactory when many different radars were used.

MK III IFF

The Mk III IFF was Watson-Watt's invention and the precursor of modern IFF systems. IFF challenge and response were to occupy a separate, specialized band (A-Band; 165 to 185 MHz or 157 to 187 MHz, depending on the reference text). It was adopted as the standard Allied IFF of World War II and remained in US service for sometime after the war. An important design criterion was to ensure that the returning signals gave an accurate indication of target bearing and not merely of target range. The solution was to locate the IFF interrogator on the radar antenna, rotating with it to give directional indications. The same device would also receive the response. This was known as an 'interrogator-responder' system. Mk III was distributed to all Allied forces including the Soviet Union. From a post-war point of view, it could be considered thoroughly compromised.

Because the system relied on active responses from other ships and aircraft, there were no problems with sea returns. It was possible to use vertical polarization, thus giving better vertical coverage. The transmitters also required much less power for a given range so the fitting of IFF presented few space problems. Initially, the interrogator aerials consisted of directional Yagi arrays mounted on a horizontal U bar, but in 1944, the most commonly used aerial system consisted of four, broad-band cage dipoles in a rectangular configuration and capable of powered rotation.

Reports on the value of IFF varied, according to the theatre of operations. They ranged from "worked very well" to "never saw it used once in two years at sea."

MK IV IFF

Back in the United States, the NRL designed an alternative system designated Mk IV. It differed from the Mk III system by employing separate frequencies (470 and 493.5 MHz) for challenge and reply. Mk IV was generally held in reserve during the war in case the Mk III was compromised. A few were used in the Pacific theatre at the end of the war. In Europe, it was not used due to its closeness to the frequency of the German Würzburg radar that operated at 550 MHz. A German radar operator might discover IFF pulses from Allied aircraft, thus compromising the system. Due to its higher operating frequency (G-band), Mk IV had greater directivity and the typical beam width was 7 to 10 degrees.

MK V IFF

Mark III was an interim measure and the NRL was directed to produce a new system that became Mk V/UNB (United Nations Beaconry). Wider transmitter and receiver frequency separation permitted the use of higher gain antennas and higher frequencies (950 to 1150 MHz) made for better directivity. Twelve channels were made available within this range as an anti-jamming measure. Signals were coded to permit, for example, identification of one among several 'friendlies'. On a Plan Position Indicator (PPI) display, transponder coding would be displayed as a dot and dash elongation (radically) of the target pip. The first Mk V systems appeared in August of 1944 but the system did not complete service evaluation until 1947-48. Mk V was considered successful but few were produced. Installations were confined to CVB's and fleet carriers where it was important to be able to track and identify fast targets such as jet aircraft. As an example, Mk V could identify a jet aircraft flying at 175 mph at 20,000 feet. An attempt was made to re-design and simplify the Mk V system. It was designated as Mk VI.

MK X IFF

The follow up system to Mk V was Mark X, a system developed in the USA. At first, this did not mean a jump from the fifth to the tenth Allied IFF system. The X denoted an experimental system and after it went into production, it assigned the Mk X (ten) nomenclature. There were problems with the Mk V system. It used a universal 'code of the day' to distinguish friend from foe but the NRL considered this a serious, potential security risk. Another danger in the Mk V was enemy use of Allied IFF to identify our own craft. By July 1952, the Mk X system started

operational use in 50 per cent of the US Navy. The balance of the fleet was to be converted by January 1954.

The Mk X IFF system sends a pulsed secondary signal from its Interrogator along with the main radar signal. This in turn is received by a Transponder situated in the craft under observation. The Transponder then sends back an appropriate reply that is detected by the Interrogator and distributed for display. Separate pre-set frequencies are used for interrogation and reply; 1030 MHz for transmission and 1090 MHz for reply. Normally, the IFF antenna will rotate in synchronism with the main air warning radar thus enabling the responses to be superimposed on the radar picture.

Three modes of operation are available for General, Personal and Functional identification. The mode of operation is determined by the spacing between the two 1 microsecond pulses which constitute the interrogating signals. Spacings employed are 3, 5, and 8 microseconds for modes 1, 2 and 3 respectively. The transponder reply to each of these interrogations is a single one microsecond pulse except in the case of an aircraft in which the reply to a mode 2 challenge is two, one microsecond pulses spaced 16 microseconds apart. In addition, the aircraft has the facility of an emergency reply consisting of four, one microsecond pulses spaced by 16 microseconds between adjacent pulses. A transponder will always reply to a mode 1 interrogation but replies to interrogation in modes 2 and 3 are optional. This is dependent upon the setting of appropriate switches on the transponder control panel. When set to emergency mode, the aircraft transponder will transmit the four pulse reply to all modes of interrogation.

MK XII IFF

Mark X did not provide real security. Its interrogation pulse was not coded. There was always a possibility that an enemy might use Mk X interrogation pulses to induce US aircraft to identify themselves and then use the aircraft's IFF system as a homing beacon for missiles. As early as 1951, the NRL had developed a vacuum tube binary coder but it was too massive for airborne use. Transistor technology improved matters. By 1956, an American tri-service group had been formed to implement what has now become the Mk XII system, the current system in use.

This is a fully cryptographic system so even if the enemy had full knowledge of the system design, it cannot be used unless the correct interrogation and response codes are known.

Modern day IFF systems are basically Question/Answer systems. An interrogator system sends out a coded radio signal that asks any number of queries, including: Who are you? The interrogator system is frequently associated with a primary radar installation, but it may also be installed aboard a ship or another airplane. The interrogation code or challenge, as it is called, is received by an electronic system known as a transponder that is aboard the target aircraft. If the transponder receives the proper electronic code from an interrogator, it automatically transmits the requested identification back to the interrogating radar. Because it was developed as an adjunct to the primary echo-type detection radar and is usually used in conjunction with a primary radar, the IFF system is also known as secondary radar.

Modern IFF is a two channel system, with one frequency (1030 MHz) used for the interrogating signals and another (1090 MHz) for the reply. The system is further broken down into four modes of operation, two for both military and civilian aircraft and two strictly for military use.

Each mode of operation elicits a specific type of information from the aircraft that is being challenged.

Mode 1, which has 64 reply codes, is used in military air traffic control to determine what type of aircraft is answering or what type of mission it is on.

Mode 2, also only for military use, requests the "tail number" that identifies a particular aircraft. There are 4096 possible reply codes in this mode.

Mode 3/A is the standard air traffic control mode. It is used internationally, in conjunction with the automatic altitude reporting mode (Mode C), to provide positive control of all aircraft flying under instrument flight rules. Such aircraft are assigned unique mode3/A codes by the airport departure controller. General aviation aircraft flying under visual flight rules are not under constant positive control, and such aircraft use a common Mode 3/A code of 1200. In either case, the assigned code number is manually entered into the transponder control unit by the pilot or a crew member.

Altitude information is provided to the transponder by the aircraft's air data computer in increments of 100 feet. When interrogated in Mode C, the transponder automatically replies with the aircraft altitude. Ground interrogators normally interlace modes by alternately sending Mode 3/A and Mode C challenges thus receiving continuous identity and altitude data from the controlled aircraft.

3.1 Type 242M IFF Interrogator (Mk III)

Antenna location: TBA

Equipment location: ?

Installed : On build,1943

Removed: ?

Type 242 IFF series interrogation equipment was fitted on RCN ships in conjunction with Type 291 (and Type 275) radar sets to provide 'A' band interrogation using the standard Mark III IFF system. Interrogators could function anywhere in the 165 to 185 MHz band, but were normally used around 179 or 182 MHz (1.8 to 1.6 metres) at a power output of 1 kilowatt. The pulse repetition frequency was 125 or 50 pulses per second and the pulse length was 6 microseconds. When used with radar types 291, the 242 was fitted with aerial outfit 'ASD'. This aerial had an omni-directional radiation pattern. Type 242 was first introduced into service in 1943. The pulse repetition frequency of the main radar was counted down in ratios of 4:1 or 10:1 in the modulator which then fired the interrogator transmitter. Simultaneously, a secondary trace, displaced from the main trace was displayed as an 'A' scope presentation. Interrogator signals received by the responder unit were displayed on this secondary trace as inverted signals along with the normal radar echoes. Correspondence of the interrogator pulse and the radar echo identified the target.

The associated shipborne transponder was the type 253 or the Mark III IFF when fitted on an aircraft. **Haida was fitted with the 242WC and 242WS types in the mid 1940's.**

Type 242 was used with types 271 (and 275) radar
Type 242M was used with radar types 293 (and 276/277).
Type 242P/Q were used with radar sets 960/982/983.

Frequency band: 165 to 185 or 159 to 189 MHz (covers all variants)

tour of duty in Korea. *(Photo courtesy RCN)*

3.2 Type 253P Transponder

Antenna location: TBA

Equipment location: ?

Installed : On build in 1943

Removed: When the IFF MK X system was installed.

Type 253P was a shipborne transponder, compatible with the Mark III IFF system and operated in response to triggering pulses from any interrogator or radar set in the same frequency band. When triggered, Types 253P/Q responded with various coded signals as required for the purposes of normal interrogation or ship-to-ship identification or homing. This set could operate in the 157 to 187 MHz band but normally operated at 182 MHz for ship-to-ship identification or when used as a beacon facility. In a normal fit, aerial outfit 'ASH' was used. For installation aboard coastal craft, aerial outfit 'ANT' was used. Normally the power output was 10 watts. A low power setting of 0.75 watts was available as an anti-direction finding measure. The pulse repetition frequency was triggered by the receipt of signals from interrogators of radar sets. This was limited only by a 300 microsecond period of quiescence between each transmission. The pulse length of the output signal could be set for narrow (6-10 us), wide (17-25 us), or distress mode (80 us).

Types 253P and 253Q were similar except that type 253Q was mounted in a resilient steel cabinet. By operating the buttons marked 'T', 'A', and 'B' on the code selection unit, the following operating conditions were permitted:

I: Normal Mark III IFF responses (sweeping 157-187 MHz every 2.8 seconds). Six codes were available by selection and each code consisted of four transmissions using narrow and wide pulses. A complete code was transmitted once every 11.2 seconds. A special extra wide pulse was available for distress purposes.

A: Alternate normal IFF codes consisting of four narrow pulses for 5.6 seconds followed by 5.6 seconds of Identity Code on a fixed frequency of 182 MHz. This code consisted of two letters that could be of any combination of nine narrow, wide or blank pulses which were selected by means of the nine switches on the Code Selection Unit.

C: Chopped response on the frequency of 182 MHz. The response was mechanically interrupted for 40 milliseconds every one-fifth second to distinguish it from a normal code.

To limit mutual interference, the antenna for type 253P was situated at least 12 feet or more from the nearest interrogator antenna on a ship. Haida was fitted with the type 253P transponder during the mid 1940's.

3.3 AN/UPX-1A IFF SYSTEM (Mk X)

Antenna locations: One antenna on port and one on the starboard side of lower yardarm on the foremast.

Equipment located: In a rack in the EMR compartment .

Installed: Believed to be 1958, when the EMR was created.

HAIDA paid off with this type.

When HMCS HAIDA paid off, her Mark X IFF fit is listed below. Most of the equipment was fitted in the EMR compartment while it was in service. All that remains today of the original system is a single AS-177 antenna on the foremast yardarm and a C1008/UPA-24 box which was located after 1992.

UPX-1A SYSTEM COMPONENTS

- * AN/UPA-24 /KY80 IFF Video Decoder
- * AN/UPA-24 /C1008 Radar Set Control (in Operations Room)

* AN/UPX-1A /RT-194A IFF Receiver-Transmitter (for IFF dipole in front of SPS-6C feed horn)

* AN/UPX-1A /KY-61A IFF Coder/Decoder

* AB-274 IFF Dipole antenna assembly in front of SPS-6C feed horn

* AN/UPX-5 /RT-269 IFF Receiver-Transmitter (for dedicated IFF antenna on foremast yardarm)

* AN/UPX-5 /KY-

88 * AS-177 IFF Decoder
Antenna Assembly (dedicated to UPX-5). 1090 MHz TX/ 1030RX

* AN/UPM-99 Radar Test Set

* AS-177 Antenna Assembly (dedicated to UPM-99)

These devices were shown on the ship's drawing as intentions but were never installed:

* AN/UPA-38 /KY-136 Video Coder

* AN/UPA-38 /C1407 Radar Set Control (in Ops Room)

RT-194/UPX-1 . This the IFF interrogator. Comprised of a receiver/transmitter whose output connects to the IFF dipole in front of SPS-6C feed horn. (Photo courtesy *Destroyer Escort Central*)

SPECS: Tx Freq. 1090 MHz, Rx Freq.1030 MHz. Average power - 1 kw. using Modes 1, 2 and 3. Mode 1 and 2 was a Naval and Air Force mode. Mode 3 was also a airborne civilian mode. The UPX-1 transmitting mode was also controlled by the AN/UPX-24".

Haida's IFF Interrogation Initiation System (Drawing by Jerry Proc)

3.4 AN/UPM-99

This was the IFF test set used to test the Mk X IFF system. The UPM-99 simulated the responses of aircraft transponders, and in doing so, the shipboard technicians could verify the correct operation of the UPA-24/C1008 decoder for each radar display fitted with IFF. The safety of the ship depended on this equipment for if the aircraft in question did not respond with the right set of codes it would be declared as hostile.

Radar Test Set AN/UPM-99 is designed for testing and performing corrective maintenance on IFF equipment of both the Mark X and SIF (Selective Identification Feature) type. It can also be used for making various tests required for maintenance of other radar equipment operating within the 925 to 1225 MHz frequency range.

The entire test set incorporates 88 vacuum tubes and 72 solid state diodes and was introduced in 1960. It was intended for HMCS HAIDA but was never fitted.

From bottom to top: PP-2391 Power Supply; SM-189/UPM99 Code Simulator ; TS-1253-UP Radar Test Set; CY-1156/UPM-4 Accessory Box. The TS-1253 unit can function separately since it has an internal power supply and incorporates the functions of a precision oscilloscope and SIF code generator. (Image credit unknown)

4.0 ASDIC/SONAR SECTION

INTRODUCTION

The first device used to locate submarines is called Asdic (named after the Anti-Submarine Detection Investigation Committee) and was invented during World War I by British, American, and French scientists. This system located underwater objects by transmitting an acoustical pulse of energy, then listening for any echoes returned from that object. From ASDIC, the more modern term SONAR was borne, which means SOund NAvigation and Ranging. SONAR is an American term dating from World War II and is now used universally to describe all underwater detection equipment. In the RCN, the term SONAR started coming into general usage around 1955 and in the Royal Navy, around 1964.

A problem with early Asdic's was their limited search ability as the oscillator projected its cone shaped beam at an angle of 10 degrees from the horizontal. Below the beam of acoustical energy was a considerable amount of dead space that would permit the target to elude Asdic. If the enemy escaped detection, depth charges had to be dropped by estimating the target's position. Wartime experience showed that this dead zone was even larger than envisioned because submarines could dive far deeper than was originally thought possible. As a result, a clever submarine commander could often manoeuvre out of harm's way. Once contact was lost, it was very difficult to re-establish.

When operating in conjunction with other detection ships, it was very important that all the operating Asdic's were tuned to different frequencies. If an operator was negligent of this, a transmitted pulse from another ship's Asdic would be detected as an extremely loud echo on another set. The operators' ears would experience the threshold of pain as the amplified echo thundered in his headphones. The Asdics developed during the war operated on a number of discrete frequencies between 14 and 22 KHz. Power output of oscillators was inversely proportional to the operating frequency. Many operators favoured operation in the 14 to 15 KHz range because they believed that greater ranges could be obtained as contrasted by operating at 18 to 20 KHz. It was well known that greater ranges could be had at 10 or 12 KHz, but that meant increasing the oscillator size. It was a trade off.

Asdic set designs generally fell into one of two categories depending on the type of Asdic dome. In the first type, the oscillator was housed in a dome fixed to the bottom of a vessel near the bow. The second type was housed in a retractable dome that could be positioned inside a chamber built into the hull of a vessel. Normally, this last type was fitted into vessels whose operations could damage an unretracted housing. Destroyers, which could damage their domes while operating at high speeds, and minesweepers, which could foul Asdic domes with their sweeping gear, were typically fitted with a retractable dome. To protect Asdic sets from ice damage, the RCN decided to fit all new vessels with retractable domes in mid-1942. When the dome was in the housed position, it precluded using Asdic. Corvettes, Fairmiles and converted yachts that only incorporated the most basic of necessities, did not have retractable domes. As a result, many of these ships sheared their domes by striking logs or chunks of ice off the coast of

Newfoundland. These fixed installations were not very successful but it was better than not having any system. When corvettes discovered a U-boat lurking in the depths, it became practice for the corvette to try to drive the U-boat underwater where it was slow and nearly blind, then return to the convoy. Trying to overtake the U-boat was pointless since the surface speed of the U-boat was slightly higher than that of a corvette. Later on, design improvements produced a sword shaped oscillator whose physical appearance resembled that of a sword and the angle from the sword to the bow could be altered to detect deep targets. In some Fairmiles, the oscillator was fixed to the hull and to train it on a new bearing, the ship would have to be turned. The standard procedure was to steer on the contact while altering course in a cast off fashion and back on again until the ship was able to drop depth charges.

From its inception in 1917 until the late 1940's, the detection range of Asdic remained at basically 2000 yards. True, during World War II, there were refinements in fire control and depth measurement, but the range remained much the same. If conditions were ideal, a target at a range of 3000 to 4000 yards could be detected and but that was the absolute limit. Contrast this to today's hydrophone technology that can detect the propeller noise of a diesel electric submarine at distances of 100 nm. A modern system can also identify the class of submarine by comparing the hydrophone signal to a pre-loaded signature in the memory of a computer. Tactically, an Asdic that only produced a narrow beam was very useful for attack, but not for search, since it could not look rapidly in many directions. It was not until the end of World War II that 'true' search sonar was introduced into the world's navies.

ASDIC OPERATIONS ABOARD HMCS HAIDA

Wilf Knecht of Nanaimo, British Columbia was a former Asdic rating and he provides an impression of Asdic operations aboard HMCS Haida during the 1944/45 period."A normal duty watch consisted of two operators manning the equipment. The Asdic recorders were located in a cabin below the bridge, on the port side and off the plot room. Under normal conditions, one rating operated the Asdic and communicated with the bridge using voice pipe while the other stood by. Both operators took turns in the active position.

When Action Stations were sounded, three operators sat on a bench in front of the Asdic and actively manned it. An HSD (Higher Submarine Detector) monitored the proceedings. On the left side of the bench, sat an operator who read out the bearing if a contact was acquired. Any rapid change or loss of bearing also had to be reported to the bridge. The centre operator operated the training control, raised and lowered the dome and controlled the firing of the depth charges. The right most rating would operate the range finder. A gyro compass repeater was provided for use by the middle operator and a magnetic compass was also fitted in case the gyro failed. When using a magnetic compass, a stop watch had to be used to establish range.

When leaving or entering harbour, the Captain or Officer of the Watch would inform the Asdic hut when to lower or raise the oscillator dome. It had to be raised if Haida was steaming above 20 knots or dome damage would result. Sometimes this was forgotten by the bridge and the Asdic operator would have to request permission to raise the dome. Operators did not search the sea at random. The normal search procedure in most cases was given as: set range to 2000 yards and begin search from Red 30 degrees to 5 degrees past the bow. If no echo was returned on the

given bearing, the operator would search from Green 30 degrees to 5 degrees past the bow. This sweep was repeated until ordered otherwise or a contact was made. If a contact was made, the range recorder operator would reduce the automatic transmission time to eliminate the lag time between transmissions as the target drew closer to the attacking vessel.

Every contact had to be classified for type, distance, direction and be reported to the bridge immediately. Operators had to be aware of the Doppler effect, which is a change in pitch of the echo as the target moved closer or more distant. The operator had also had a chance to demonstrate his skills in determining if an object was a whale, tide or water conditions, large schools of fish, rock formations or old wrecks." One point that Wilf highlights is the fact that there was no documentation issued to Asdic ratings due to the prevailing level of secrecy. Jim Fairnie of Victoria B.C. recalled another side to this secrecy. "Asdic operators were prohibited from wearing Asdic badges on uniforms while at sea in case their vessel was torpedoed and they were picked up by the enemy. To add to the disguise, the operators wore a torpedoman's badge."

Because Asdic transmissions were audible by their nature, operators had to wear headphones to hear the incoming echoes. Since it was also necessary to communicate with the bridge, the operator could not keep both ears covered so the one earpiece was placed against the side of the head and then switched occasionally. If a contact was acquired during Action Stations, its echo could be patched into the ship's loud hail to keep everyone informed as to status. When not operating Asdic, operators would be assigned to the plotting table or the depth sounder."

John Coates explains his role in Haida's Asdic room. "In action, I took up my station behind the operators and wore my chest set. This was merely a set of headphones and a chest microphone. One earpiece was wired to monitor the contact and the other was connected to the bridge/ops room circuit along with the microphone. There was an extra long lead on the headset so I could step around the corner and see the Plot.

If I wanted the most current contact status from any of the operators, I would touch them on the shoulder as part of an established drill. We did keep a continuous flow of bearing and range information to the bridge and the Plot and consciously kept the verbal chatter to a minimum.

Rear Admiral Bob Welland (Ret'd) of Ottawa Ontario, relates some of his wartime experiences as CO of Haida and Assiniboine. "The CO's of the ships in a squadron or group got to know each other well and usually had opportunities to discuss the last operation and the up and coming one. We also compared our habits at sea. For instance, I stayed up at night because that's when the action happened and I knew that the Officers of the Watch could handle the situation in daylight. Also, I never got undressed except to wash up. I arranged an Asdic gyro indicator to be fitted in my sea cabin along with a speaker that pinged if an echo was detected. Upon hearing an echo, I would wake up and using the voice pipe, I would have the ship turning before making it up the ladder to the bridge. I was not alone in this. Many of the senior operators and the HSD's slept in the Asdic office for the same reasons.

Over time, it got to the point where the CO's of various ships created a 'pool' and took bets as to which ship would be torpedoed or be in collision. I won twice but had to share the pot with another Captain."

4.1 SONAR INSTRUMENT SPACE

All the Sonar/ASDIC electronics was located in this space. Transducers were situated in the Hull Outfit 7A. Indicators and controls in the Sonar Control Room and one type 164 indicator in the Operations Room.

4.2 Type 144Q Search Sonar

System installed: On-build in 1943

System removed: Likely during 1950-52 modernization.

HAIDA'S equipment manifest of the mid 1940's lists the installation of the 144Q Asdic set. Both the 144 and 145 sets were designed to be used with ahead throwing weapons such as Hedgehog but could easily be used with depth charges. This new development in Asdic technology made its service debut in May of 1943. The main features of the 144Q set are described below.

The Q attachment was an additional Asdic set which required separate transmitting and receiving equipment suitably inter-connected with the main set. Physically, the Q oscillator was mounted beneath the main oscillator and trained with it. It projected a fan shaped beam that was narrower in the horizontal plane than the main Asdic beam but sufficiently wide in the vertical plane to receive echoes at any angle from the horizontal to 45 degrees below horizontal. The beam was only 3 degrees wide on the horizontal plane. Collectively, this new arrangement enabled contact to be maintained with deep targets at short ranges and also minimized the dead zone. The Q beam was transmitted through a window in the bottom part of the dome.

This arrangement allowed the Q oscillator to be used at angles of up to 70 degrees from the bow. In shallow water, the Q beam would strike the bottom giving long drawn out echoes that appeared similar to heavy reverberations. This effect made the Q beam appear stronger than the main beam but the effect disappeared in deep water.

Range

The transmission range was selectable between 1000 and 2500 yards.

Frequencies

The main set could operate at any one of a series of fixed frequencies. In KHz as listed:

Y 14

A 15

B 16

C 17

D 18

E 19

F 20

G 21
H 22

The Q attachment operated at 38.5 KHz. To avoid mutual interference between the main set and the Q attachment, the two transmitting circuits were synchronized so that they transmitted simultaneously. During reception, Doppler shift was much more pronounced on the Q beam as opposed to the main beam.

Oscillator

The Q oscillator was rectangular in shape, completely encased in rubber, and its dimensions were 12.5 inches long by 2 inches wide and 2 inches thick. Within the dome, the oscillator was mounted so it faced downwards at a fixed angle of 15 degrees.

Transmitter

The key operating circuit was completed by the range recorder or by Morse key. Alternately, the circuit could be closed if the send-receive key was moved to the 'Send' position. This action connected the oscillator by way of the tuning panel to the high frequency motor-alternator. A high frequency alternating current was then applied to the oscillator which in turn sent a transmission. The transmission ceased immediately when the key operating circuit was broken.

The motor-alternator set that provided the high frequency current for the oscillator, consisted of a 110 or 220 volt motor driving an inductor type alternator over a range of 4,666 to 7,333 revolutions per minute. This corresponded to a frequency range of 14 to 22 KHz. Dual motor-alternators with a change over switch were fitted to allow for maintenance on one unit while the other unit was on-line.

Oscillator frequencies were changed by opening a control box near the motor and moving the 'wandering' lead marked F (field) to a different resistance tap. The selected tap would either speed up or slow down the motor thus changing the output frequency of the alternator. The output was then fed to the tuning panel that consisted of an inductor, a capacitor and resistor. These components formed a resonant circuit that effectively stepped up the output voltage of the alternator to the 2000 volt level required by the oscillator.

It is estimated that the output power of the transmitter was in the range of 300 to 500 watts. The tuning of the receiver to match the actual transmitted frequency was most important - and the facilities to do that were not easy to understand and execute in practice.

Dome

In the retracted position, the dome protruded eleven inches below the keel and was four and a half feet below the keel when extended. A two horsepower motor was required to raise and lower the dome with a provision to do it manually. A set of indicator lamps in the Asdic office indicated the position of the dome -- red was for the working position, green was for housed and red/green for any intermediate state. In the housed position, the dome, the raft, and the oscillator

were drawn up to the top of the trunk. The top of the raft butted up against a dermatine seating ring under the top of the trunk, thus making a watertight joint. This allowed the portable cover to be unbolted, in the event that either of the oscillators had to be changed. The procedure would only work if the dome was undamaged.

The Staybrite window of the dome, was aligned with the face of the oscillator so sound waves could be transmitted and received in a 360 degree arc in 5 degree steps. Staybrite was secured over a ribbed section of heavy cast metal and this ribbing is what produced the window effect. Both fixed and retractable domes used Staybrite windows.

Maximum design speed for the dome was 25 knots but on Haida, the maximum working speed was 20 knots. When retracting or extending the dome, it was necessary to check the voltage of the mains supply. In a 220 volt mains' system, the voltage could not drop below 180 volts. If it did, the contactor in the control board could fail to operate thus causing the dome to bump against the end stops and cause damage.

The dome was normally housed for any of the following conditions: when working cables; when working bottom lines; when entering or leaving harbour; when steaming into a heavy sea; if cessation of Asdic operations could be tolerated; and finally, when navigating in shoal water and Asdic is not required for navigation.

AVC Receiver

The Automatic Volume Control (AVC) receiver was a rack mounted, seven tube heterodyne-amplifier, operating in the 10 to 26 KHz range. Any received sound would disturb the oscillator which in turn produced a weak voltage fluctuation across its terminals. This voltage was then applied through the tuning panel and the send- receive key to the input of the AVC receiver where it was amplified and heterodyned. The A.V.C. output was then fed to the Very/Quick (V/Q) changeover board. Here, the signal could be distributed to the recorder, the loudspeaker, the telephone switches or any combination of these.

Why was an AVC receiver required? When reverberations were received and were extremely loud, they drowned the echo. To overcome this problem, automatic volume control was used. Such an amplifier reduced the amplitude of loud sounds and amplified weak sounds thus producing a 'smoothed out' effect. This in itself is problematic, because echoes would not be distinguishable from reverberations. To overcome the second problem, the amplifier was designed to prevent the AVC from functioning whenever a loud sound was received. This allowed the echoes to escape the smoothing process and made to stand out very clearly against the long (and consequently reduced) sound of the reverberations.

Within the AVC receiver, there was an electronic oscillator whose output signal was mixed with the incoming signal. This is known as the heterodyning process. In the 144Q set, the difference between these two frequencies was 1000 cycles per second. This tone was then passed to the range recorder where it generated a mark on a strip of paper.

Range Recorder

This instrument was designed to visually record sounds received by the oscillator and provide an accurate range plot on paper. At the appropriate time, as determined by adjustments made to the recorder settings, it automatically actuated the release of depth charges or the firing of ahead-thrown charges.

Specially treated paper was driven by a gear mechanism and marked with a stylus. This paper was impregnated with a solution of potassium iodide and starch. Passage of electrical current through the paper from stylus to roller released 'free' iodine. The iodine was then deposited on the paper thus making a record in the form of a brown mark. When installing fresh paper records, it was imperative to minimize the amount of time that the paper was exposed to air. Within the recorder, the paper roll was stored in an airtight container known as a tank. Each roll of paper was 30 yards long and a black warning mark would appear on the right hand edge signifying the approach of the end of the roll. After its appearance, there was still sufficient paper remaining to complete the attack. Alternately, yellow coloured, cadmium-iodide paper could be used in the range recorder. Generally speaking, the range recorder was only switched on when investigating a contact and during attack.

The recorder also had a paper speed switch which had two positions. - *Cruising* and *Attacking*. In *Cruising* , the paper moved slowly, just fast enough to give a clear space for the stylus to mark on. In *Attacking* mode, the paper moved at a faster speed. The object of the switch was to save paper by providing a slow paper speed when sweeping. When sweeping was initiated, the range recorder operator had to see that the paper speed switch was set to *Cruising*. On gaining contact, the switch was set to *Attacking* .

To summarize, the range recorder has two jobs. One is to make the transducer train and transmit when it should. The other is to mark the echoes on the paper and indicate the time to fire the A/S weapon. The recorder is fitted with control switches. They are the barrel switch with four positions, the scale change switch and the paper speed switch. It also has a handle to adjust the transmission interval.

Bearing Recorder

This instrument indicated the gun bearing when carrying out an ahead-thrown weapon attack against a submarine. An adjustment was provided to make allowance for ship's own speed and the sinking time of the charges. The bearing recorder was used in conjunction with the range recorder from which it obtained the necessary impulses for the paper drive motor.

144Q Bearing Recorder. (Photo courtesy of the British Admiralty)

Operating the 144Q Asdic

Harry Carson provides a detailed explanation on the operation of the 144Q stepping switch. "The stepping switch was a spring loaded, stepped switch, mounted in the centre of the training wheel. When the switch was moved to the right, it would train the oscillator to the right. If the switch was released by the operator, the training mechanism would reverse the direction of rotation and set the oscillator to the same angle as the switch setting. The oscillator would be kept in that direction until the operator heard an echo. At this time, he tapped the switch and continued to do so each time an echo was heard. The oscillator would then be trained off the contact by the control mechanism until the First Operator would receive no echo. Next, the stepping switch was reversed and the training mechanism would reverse direction. The Operator would then tap the switch sharply when the echo was heard. Again, the stepper switch would be reversed and

repeated until the bearing 'cut-on' could be determined. Additional repetitions of this procedure allowed the operator to determine right cut-on, left cut-on, extent of target and bearing movement. This data along with information on the echo Doppler would be reported to the bridge.

In the Operations room, the data was plotted on the A.R.L. Plot in preparation for the depth charge attack. If the echo was lost and the 'lost contact' procedure failed to relocate the echo, the A.R.L. Plot would assist the Anti-Submarine Officer (A/S C.O.) in estimating the position of the sub based on the A.R.L. Plot layout. The A/S C.O. would then give the operator a new sector to search. This would still not guarantee that the contact would be found as both the hunter and the hunted may have gone around in circles."

4.3 Type 147B Depth Finding Set

Supplement to Type 144Q

System installed: 1943?

System upgraded to 147F during 1950-52 modernization ?

The 147 type was a depth finding set that complemented the main Asdic set (144Q and the Q attachment). Its most notable feature was its sword shaped oscillator operating at a frequency of 50 KHz. Physically, the sword was four to five inches wide and approximately four to five feet long. To prevent interference with the main set, the 147 was mounted ahead of it. When not in use, the sword was stored in a lifting tube mounted within the hull. When deployed, the sword could project a fan shaped beam being narrow in the vertical plane and wide in the horizontal plane. It could be trained up to 65 degrees horizontally and 45 degrees vertically. This new design, which added depth determining capability, could accurately track a target within 20 feet. Another feature was its integration with Squid, an ahead-throwing Anti-Submarine (A/S) mortar. Together, they formed the most effective A/S weapons system of World War II. When an echo was received on a 147B set, the operator would tilt the sword until the echo was lost. He would then reverse the procedure until the echo was heard again, then continue sweeping until the echo was lost on the opposite end of the sweep. Every echo received would then be printed on the depth recorder. A line of light on the depth recorder would indicate the centre of the echo trace. The operator would then look at a calibrated scale and read off the depth directly in feet. From here, the information was used for setting the pistols on depth charge fuses or transmitted to the Squid mount. When Hedgehog was fitted, depth information was not applied, since this weapon had to strike a solid object before it exploded.

New style recorders automatically gave range and direction for steering, while the set itself could automatically set and fire Squid mortars. After the war, it was calculated that a well trained 147 team could achieve a 50 per cent kill rate, nearly nine times that of depth charge system and substantially more than Hedgehog. The 147 set was first tested in March of 1943 and entered service with the Royal Navy in September of that year. It cannot be ascertained when the RCN was informed of this new Asdic type, but discussions for procurement of the 147 did not begin until September of 1943. Eventually 150 of these sets were ordered with the intention of eventually retrofitting all RCN escort ships. A 147F set was fitted on Haida and was complementary to the 164B attack sonar.

Harry Carson also adds, "While serving in HMCS Haida from March 15, 1952 to September 24, 1953, the sonar on board was not used extensively in the Korean Campaign as the North Koreans had no submarines. Gunnery was the major weapon of this war although we swept for hydrophone effect especially when sighting Junks along the coast."

Type 147F Depth Finding Set.

Used in conjunction with 164B set
 System installed or upgraded: ?
 HAIDA paid off with this type

4.4 Type 162

Notation found on 1952 HAIDA drawing along with 147B set.
 System installed: ?
 System removed: ?

The book “Seek and Strike” describes the 162 as a bottom contact classification set for detecting submarines or bottom wrecks. See AN/SQS-501.

4.5 Type 164B Range and Bearing Finding Set

Used with Ahead Throwing Weapons such as Squid.
 System installed: ?
 HAIDA paid off with this type

This Asdic set was mainly fitted into frigates and Tribal class destroyers and designed to be used with Hedgehog or Squid (mortar bomb). It incorporated a quartz transducer and the Q2

attachment that is well documented in the 144Q section. In many ways, it was very similar to the 144Q set. The type 164 was a range and bearing finding device that was supplemented with depth data from the 147F set. If fitted on a frigate, then Hull Outfit (dome) number 3 would be used. For Tribal Class destroyers, Hull Outfit 7 or 7A was used. On Haida, both the 164 and SQS-10 transducers were fitted into Hull Outfit 7A. The type 164 bearing repeater was a large mechanical indicator with bearing pointers.

4.6 AN/SQS-10 Search Sonar

System installed: During 1950-52 modernization
HAIDA paid off with this type

The AN/SQS-10 sonar was called an azimuth scanning AM type since it transmitted and received omni-directionally. When HMCS Haida was paid off, she was fitted with this sonar type, so it will be discussed in greater detail. SQS-10 sonar was granted 'AN Nomenclature' type number in 1950 and manufactured by Sangamo Electric. Unlike the wartime Asdic sets, this unit did not use a quartz oscillator. Instead, it was replaced with a transducer -- a device that produces underwater sound based on the magnetostriction principle. Unlike the 2000 yard limit of the wartime Asdics, this set could operate out to 6000 yards under ideal conditions when echo ranging.

What is Magnetostriction?

When an iron rod is placed inside a coil and a direct current (DC) is passed through the coil, the iron will lengthen. This is known as an electromagnet. If the current is reversed, the rod will again lengthen. By substituting alternating current (AC) the rod can be made to vibrate at twice the applied frequency. The amount of lengthening is also dependent upon the material used and its magnetization properties.

To overcome the doubling effect, a DC polarizing current is applied to the coil. This causes the iron rod to lengthen and stay lengthened by a certain amount. If AC is applied on top of the DC, the rod lengthens even farther during the positive half cycle but returns to its normal length during the negative half. The frequency of the applied AC is selected to be close to the natural

resonant frequency of the rod. By bundling multiple electromagnets and attaching the ends of the rods to each of two plates, a pulse of sound can be produced. One plate, which is thicker than the other is known as the base and the other plate is called the diaphragm.

Research indicated that nickel was an ideal material to use in the construction of a transducer since it has a characteristic to retain residual magnetism. This magnetism assists with the production of the polarization field. An alternate method to manufacture a transducer would be to use laminated nickel-iron stampings instead of rods. Each of these electromagnets was called a stave or an element.

Transducer Construction

The SQS-10 transducer was cylindrical in shape and operated on the magnetostriction principle. Externally, the transducer is covered with a heavy rubber jacket or boot to keep the internal elements watertight. Electrically, it was two transducers in a common housing. The SEARCH section consisted of 48 vertical staves arranged into four sections. Each stave contained nickel laminations and a polarizing magnet and was electrically independent of the others. Located directly above this array of staves was a second ring of staves that formed the second transducer within the common housing.

This second transducer was used for echo ranging when the target was too deep or too close and the ship was about to pass over it. Since this second transducer permitted the target contact to be held until the last moment, this transducer was called the MAINTENANCE OF CLOSE CONTACT (MCC). The MCC mode was switch selectable from the operator's console.

There was no need to rotate a transducer of this type since the 48 staves covered an arc of 360 degrees. When training the audio system to the bearing of the target, it was a case of simply enabling the staves on which the returning echo or hydrophone effect was the loudest. This was done with the audio scanning switch. A transducer transfer switch selected the normal or MCC portions of the transducer.

AF/RF Amplifier (AM-580/SQS-10)

The primary purpose of the AF/RF Amplifier was to amplify the audio frequency or radio frequency signals received from the 48 staves of the transducer and pass them across the audio and video scanning switches. In addition, the unit contained the keying relay, also known as the send/receive key.

Receiver Scanning Switch Assembly (R433A/SQS10)

This was a cabinet that contained a three channel receiver, the master oscillator and the audio/video scanning system. Pulse lengths from the oscillator were adjustable for 7, 35 or 100 millisecond intervals. One channel of the three channel receiver was used for the audio signal. The other two were used as a twin channel receiver for the video portion of the system. A sum-difference switch on the operators console determined whether they acted as two separate receivers or as one. This affected the display on the CRT mounted in the operator's console. In sum, any echo or noise will brighten, but as only as a large mass. If switched to difference, a sharp, clear spot was displayed.

The video scanning switch differed greatly from the audio scanning switch. It consisted of 48 staves rotating at 3000 revolutions per minute, thus giving 9000 scans per minute. Its rotor was divided into a right and left half which permitted the twin channel receiver to be used as either a single unit, or as two separate receivers. Through means of a 2:3 gearing ratio, the rotor was connected to a sweep generator. This generator controlled the rotation of the spot on the cathode ray tube and also the distance that the spot moved from the centre to the outer edge of the CRT. Visually, a small blotch of light was produced at the centre of the CRT and blossomed out into a circle by the time it reached the edge of the CRT.

Transmitter (T318-SQS10)

This assembly contained the power amplifiers for the transducer when echo ranging was used. The 20 KHz signal produced by the master oscillator was amplified and connected to the

transducer by means of the keying relay and the transducer transfer switch. Connecting to this cabinet was the capacitor panel whose operating voltage was 8000 volts. Output power was reduced when operating at close range. Power was also reduced when mutual interference between ships was being experienced.

Signal Data Converter (CV200/SQ)

This instrument, as used by the RCN, converted the relative bearings of signals into gyro bearings. It produced the stern bearing indicator and if the gyro failed, it would automatically change the bearings back to relative.

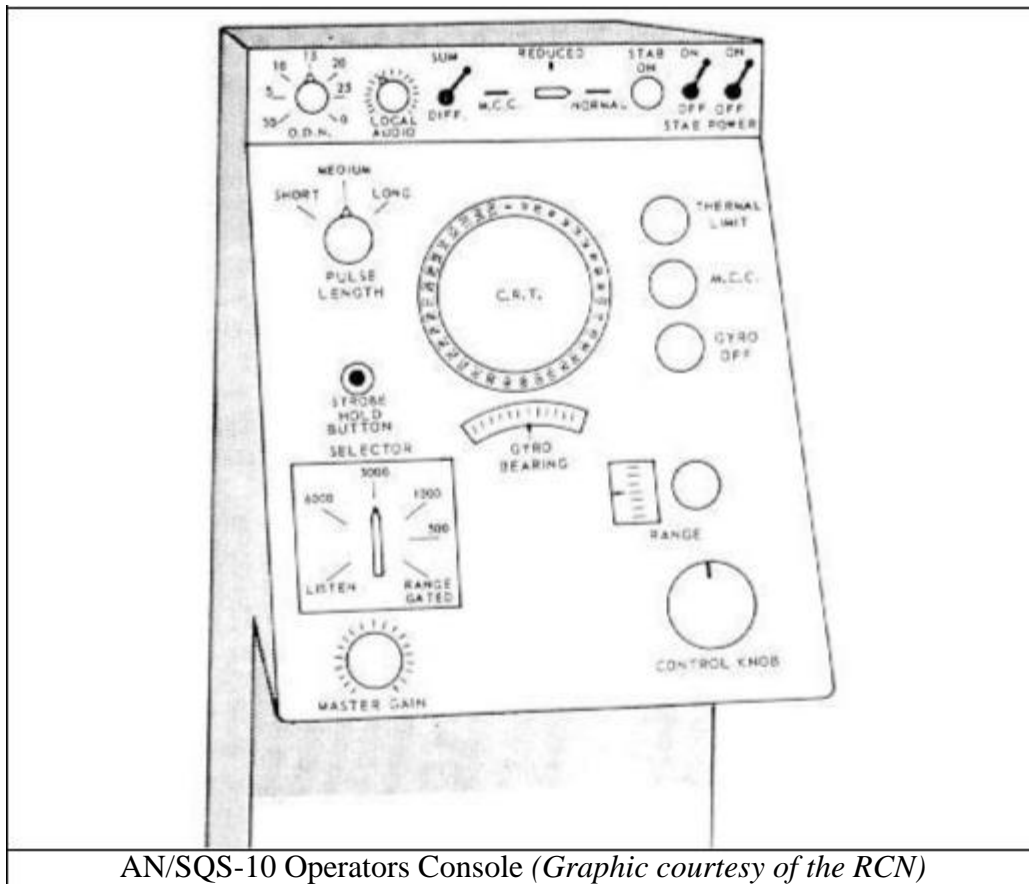

Control Indicator (C935/SQ)

The control indicator was the operator's position and contained all necessary operating controls. Some of the functions have already been discussed, so readers are referred to an illustration of the SQS-10 operator's console.

Azimuth-Range Indicator (IP165/SQ)

This was a slave repeater unit that had its own controls for speaker volume, focus, signal intensity, and CRT intensity. It duplicated what the operator was seeing on his console - a spiral sweep expanding and all the returning echoes or sound spokes (Hydrophone Effect-H.E.) and the bearing cursor. A red plastic disk could be used to protect the phosphor coating on the inside of the CRT in case it was exposed to bright lights or sunlight.

Operating Hints

Here are a few operating hints for the SQS-10 sonar quoted directly from the Sonarman Trade Group 1 Manual.

"Should you see an echo anywhere in the CRT, whether it is within the sweep ordered or not, investigate it aurally by training your audio beam on the bearing. If you have difficulty in determining Doppler, switch pulse length to long for a few transmissions. To help distinguish between a wake and or submarine echo, transmit by hand immediately after the instrument has sent out its normal transmission. Wake echoes tend to be mushy, but a submarine will reflect two distinct echoes. If it's necessary to punch through a wake to reach a submarine, it will be easier by switching to a short pulse length."

The AN/SQS-10A was developed in 1953 but an initial procurement by the US Navy was cancelled. Canadian procurements are not known at this time.

Tom Fullerton operated the SQS-10 while serving with the RCN. He recalls the following. "The SQS-10 was my favourite. I participated, with about 20 of my shipmates, in a three week course at the USN Fleet Sonar School Key West FL in July 1963, called something like "Target Aspect Using Scanning Sonar." We were shown that it was actually possible to determine the course of the submarine (+ or - 180 degrees) by examining the shape of the blip on the screen. I found that

to be easy using the SQS-10 in close range (1000 yd scale) and with the high definition switch on. I have no evidence that any of the other course participants applied their newly acquired knowledge to that technique.

When we became operational again, I was put in charge of my watch (the "SCO") even though I was still an AB at the time. I would talk over a microphone to the action plot in the Ops Room next door. The contacts were fed automatically into the plotting table using inputs from our sonar and from acoustic info (dunking passive sonar) from the helicopters. Radar ops tracked the chopper's location. There was also a lot of chatter directly from one Ops Room to another when ships were in company. Traditionally when the submarine altered course or changed speed, it would show up perhaps 2 minutes later on the plot. Individuals had no idea of the big picture unless they were watching the plot. The Captain was normally in the Ops Room during these exercises.

When I (using my new-found knowledge, plus echo pitch to eliminate the 180 thing) started to tell them that the target was altering course and calling out new headings in the middle of the course change, the folks watching the plot were at least 2 minutes behind my information. At first there was total disbelief, then a sense that there was something spooky going on. I ended up with two people who outranked me (a Leading Seaman and a P.O 2nd class) on my watch. The LS constantly complained, but the P2 was an amiable fellow from Prince Edward Island who didn't care a whit.

As the "SCO," I stood behind the 5 operators - three on the 502, one each on the SQS-10 and the SQS-503. I had a microphone and a headset. One phone was tuned to the Ops Room, the other was switchable between the three sets. I wandered along behind the operators and watched what they were doing. When we got in within 1000 yds, I would stand behind the SQS-10 operator and throw the necessary switches. I carried a small plastic ruler that I could lay against the blip and then carefully move it to the screen center to determine target course. I also had the mortar firing pistol mounted in the deckhead above me, next to the headphone switch".

4.7 AN/SQS-501 Sea Bottom Identification Set

System installed: ?

HAIDA paid off with this type

The AN/SQS-501 was an auxiliary set designed specifically for identifying submarines lying on the ocean floor where the depth of water was not too great. In the Royal Navy, this set was known as the type 162 or Cockshafar. There were three, fixed, quartz transducers mounted in the forward end of the ships hull. One unit faced port and another faced starboard. The third unit, mounted in the keel, faced straight down. In operation, either the port and keel or the starboard and keel transducers were used. They produced a sound beam at right angles to the ship's fore and aft line. This beam was fan shaped, being narrow in the horizontal and very wide in the vertical plane. A simple changeover switch provided a means of projecting the beam to port or to starboard.

The recorder produced a shadow trace that gave a reasonably clear picture of the bottomed object. By application of a mathematical formula, it was possible to determine the length and

width of the target. The transducers were mounted in hull fittings that were secured on the inside of the ship's hull. Another system equalized the pressure inside the fittings to that of outside sea water. This was accomplished with inter-connecting pipes between the hull mountings and a supply tank that was mounted inside the ship at water level. The liquid used in this system consisted of a mixture of water and glycerine. This prevented freezing and possible damage to the hull mountings in colder climates.

The port or starboard side hull openings for the SQS501 transducer look like this. This photo of HAIDA's hull was taken when she was in drydock in 2003. The hull has just been power washed, hence the lack of paint. (*Photo by Jim Brewer*)

4.8 Hull Outfit 7A (commonly, the Sonar Dome)

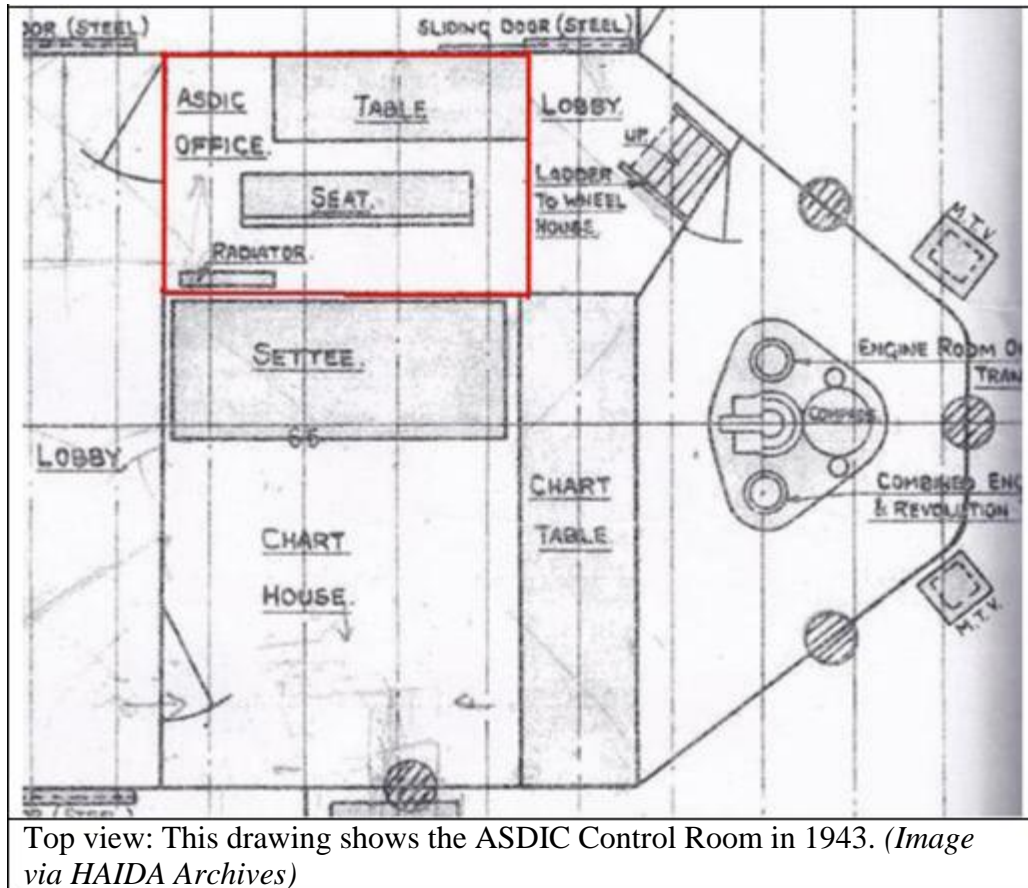

Dome installed: Likely during the 1950-52 modernization.
HAIDA paid off with this type

The maximum working speed of this dome was 20 knots however, SONAR echoes are very difficult to detect beyond 15 knots because the water rushing by the dome would mask the incoming echoes. Any SONAR dome on any ship was normally housed inside the hull for any of the following conditions: 1) When working cables or bottom lines; when entering or leaving harbour; when steaming into a heavy sea 2) If cessation of SONAR operations could be tolerated; and finally, when navigating in shoal water and SONAR was not required for navigation.

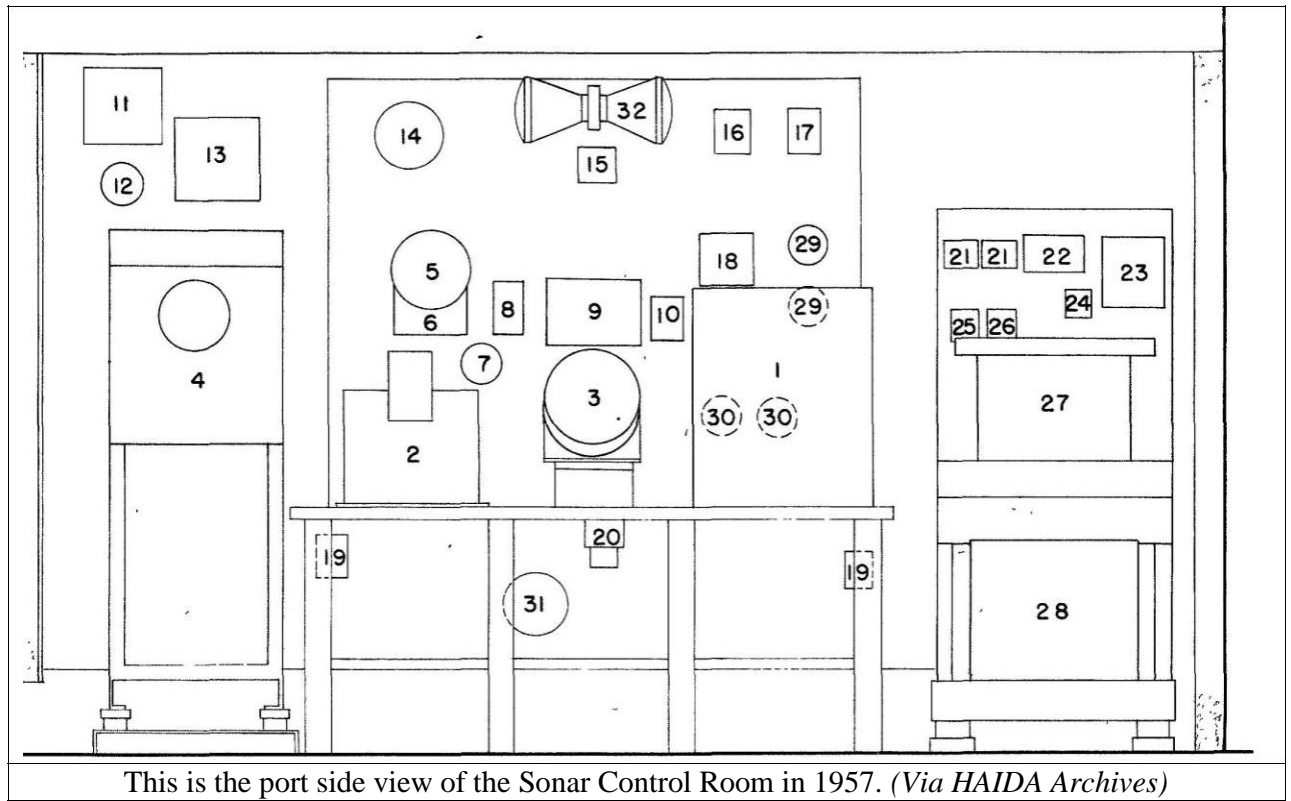

This SONAR dome, actually known as “HULL OUTFIT #7A” was part of HMCS HAIDA’s SONAR system. To protect the transducers, which are mounted within the dome, the exterior of the Hull Outfit is clad with a special type of stainless steel called Staybrite. When in operation, the dome is lowered from the hull of the ship using a hoist. It then floods with sea water, thus permitting the passage of the transmitted sound pulse and reception of echoes. Note that the SONAR dome is being displayed in an inverted position. The flange with the bolt holes would normally be secured to the hoisting mechanism. *(Photo by Jerry Proc)*

This is the equipment listing for the Sonar Control Room for 1957. (Via HAIDA Archives)

1963: Equipment ID in this photo:

- 1) Dome locator. It has three indicator lights: up--moving--down.
- 2) Gyro repeater.
- 3) 164B Bearing Recorder. It also sent a signal to readout in the wheel house. When the bridge gave the order "steer by sonar", the helmsman would follow the sonar bearing repeater.
- 4) Operator Position. By turning the knob to a new bearing, the transducer will follow to the new bearing. By pressing the knob, the sonar set transmits a single pulse.
- 5) 164B Range Recorder.
- 6) 164B Down Angle Recorder.
- 7) Barometer. It does not belong in the SCR and was placed there only to cover up a bunch of cut cable ends.

Three, small, circular gauges mounted to the plywood bulkhead do not belong there. These are pressure gauges and were mounted for a movie shoot. They have never been taken down.

The AN/SQS-10 operator's console would have been at the left side of the Sonar Control Room. HAIDA does not have an example of it. There was also a repeater for it above the VK5 slave PPI in the Operations Room. .

The AN/SQS-501 recorder is mounted on the starboard bulkhead in the Operations Room.

5.0 OTHER SOUND BASED SYSTEMS

5.1 Type 761 Depth Recorder

System installed: on build in 1943?
HAIDA paid off with this type.

Haida's equipment manifest from the mid 1940's indicates that a Model 761 echo sounding set was fitted. To measure water depth, a ship transmits an underwater sound impulse that travels through the sea at a uniform speed. On reaching the sea bed, an echo is returned which is then measured and recorded graphically. The interval of the echo is proportional to the depth of the sea.

5.2 AN/UQC-1B Underwater Telephone

System Installed: ?

HAIDA paid off with this type

This device was an underwater communication set, or as it was more commonly referred to as an Underwater Telephone. It was designed for use on submarines and surface ships to provide amplitude modulated (AM) voice or CW communication through the water using a 8.0875 kHz carrier. AM mode employed Single Side Band (SSB) using the upper side band (USB). The useable range varied between 8,000 to 12,000 yards depending on ship's speed and sonar conditions. That is the range quoted for the 'A' and 'B' variants. Morse code used a fixed audio note of 712 Hz. Personnel stationed on the ship's bridge used a telephone like device when communicating on voice.

A small, cylindrical, magnetostriction transducer was fitted in the sonar dome, aft of the main set. A combined receiver-transmitter panel was fitted in the sonar instrument space while the 'sonar set control - remote control unit' (SSC-RCU) was mounted at either the command position or in the operations room. The SSC- RCU contained a power off/on switch for the set, a loudspeaker with volume control, a Morse key, a phone/CW switch and a microphone.

A hand written note on one of the source documents for this device indicates that the RCN ordered 45 sets on the initial procurement. HMCS Haida was fitted with the AN/UQC-1B at the time she was paid off.

OTHER DATA

Manufacturers: UQC-1, 1A, 1B RCA , Camden N.J.

UQC-1D Bendix Corp, Bendix Pacific Division, North Hollywood California

Production : 1A - March 1958

1B - 1960

1D - 1962

(one Parts Manual for the UQC-1B is dated 1956)

Stock Numbers:

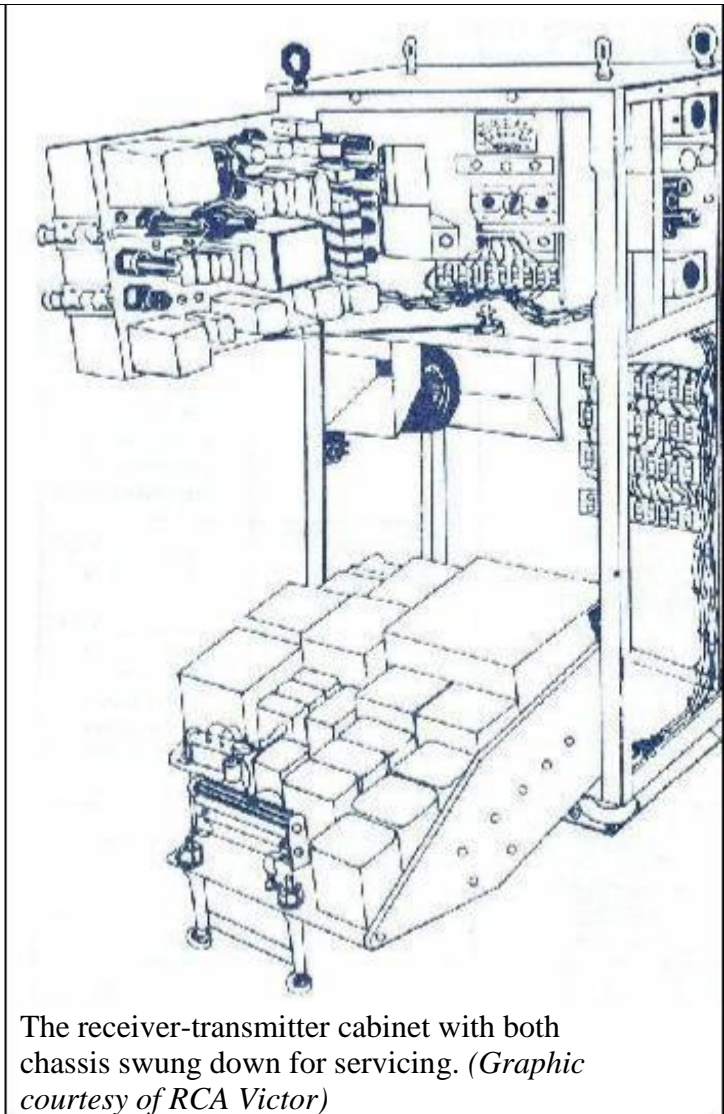

'B' variant - NATO 5845-21-041-1681.

'D' variant - NATO 5845-21-041-5083

Manuals:

Maintenance Standards for AN/UQC-1, 1A, 1B.

Bureau of Ships. NAVSHIPS 91180.42. Contract Number 71851. RCA. March 31, 1958

6.0 OTHER EQUIPMENT

6.1 4356M BOTTLE TRANSMITTER

The bottle transmitter (B.T.) did not emit any radio frequencies. This device was used to provide transmission to a group of repeater motors, such as those in a radar installation, or to step up the number of repeaters that can be controlled from a gyro-compass where it is inconvenient to use a multiple transmitter or transmitter panel. They were also used extensively where it was desired to use Admiralty type equipment controlled by some other type of gyro compass.

Bottle transmitters fell into two groups -- pattern #5356 that transmitted to M-type repeater motors and pattern #5355 that transmitted to Sperry-type repeater motors. The B.T. could operate

a load equivalent to fifteen Mark 10 M-type repeater motors at its maximum. On HMCS HAIDA, the bottle transmitter was used to transmit azimuth information from the Admiralty Mk 5 Gyrocompass to remote indicators.

6.2 RTU

HAIDA was fitted with RTU during the mid 1940's. The acronym means Range Transmission Unit (M type system). It was used to transmit radar information to remote indicators on the ship. No photo of it is available,

7.0 BIBLIOGRAPHY

To maintain the brevity in this list, extracts in this paper have been made from the respective equipment manuals whenever those manuals were readily available. Much of the other material has been extracted from the web page ASDIC, RADAR and IFF SYSTEMS used by the RCN - WWII and Post War by Jerry Proc. The document can be found at: <http://jproc.ca/sari/>

8.0 ABOUT THE AUTHOR

Jerry Proc, VE3FAB, a resident of Etobicoke Ontario, has been a licensed amateur radio operator since 1964 and also holds an Advanced Amateur Radio Operator's Certificate. His interest in electronics was sparked at a very young age and during the 1960's Jerry developed a fascination with military radio gear. In 1970, he graduated with a diploma in Electronics Engineering Technology from the Radio College of Canada. Later, he obtained an Advanced Networking Certificate through Continuing Education Studies program at Humber College, Etobicoke Ontario. Jerry has served in both a technical and managerial capacity in the mainframe computer and data communications field since 1970 and is currently retired from Bell Canada where he was employed as a network support specialist.

Jerry Proc in August 2015

His involvement with the restoration of radio systems aboard HMCS HAIDA started out quite innocently in July of 1992. It has now developed into a very engrossing and stimulating endeavour. In October 1999, his efforts to restore HAIDA's radio rooms and other significant contributions were recognized by the Historic Naval Ships Association and awarded Jerry the Bos'n Marvin Curry award, the first Canadian to receive it. In early 2001, Jerry's research work on radio and radar was officially recognized and incorporated into the Appendices of the book "HMCS HAIDA - Battle Ensign Flying" by Barry Gough.
